CHAPTER SIX
FUNCTIONS:
ADVANCED TOPICS

CSC 161: The Art of Computer Programming
Matt Post (grad TA; guest lecturer)
10/28/2009
Here we’ll walk through the execution of a function. The slides will try to make explicit the facts that (a) when a function executes, the only information it has from its calling context are variables passed in from the calling function through its formal parameters and (b) the calling function knows nothing about how the function operates; all it gets is the return value.
Here are three function definitions. We take main() to be the canonical starting point.
function definitions:

def square(x):
    return x * x

def distance(p1,p2):
    squarex = square(p2.getX() - p1.getX())
    squarey = square(p2.getY() - p1.getY())
    return math.sqrt(squarex + squarey)

def main():
    p1 = Point(2,3)
    p2 = Point(5,7)
    dist = distance(p1,p2)
    print dist

You run main()
function definitions:

```python
def square(x):
    return x * x

def distance(p1, p2):
    squarex = square(p2.getX() - p1.getX())
    squarey = square(p2.getY() - p1.getY())
    return math.sqrt(squarex + squarey)

def main():
    p1 = Point(2,3)
    p2 = Point(5,7)
    dist = distance(p1, p2)
    print(dist)
```

You run main()
function definitions:

def square(x):
    return x * x

def distance(p1,p2):
    squarex = square(p2.getX() - p1.getX())
    squarey = square(p2.getY() - p1.getY())
    return math.sqrt(squarex + squarey)

def main():
    p1 = Point(2,3)
    p2 = Point(5,7)
    dist = distance(p1,p2)
    print dist

You run main()
function definitions:

def square(x):
    return x * x

def distance(p1,p2):
    squarex = square(p2.getX() - p1.getX())
    squarey = square(p2.getY() - p1.getY())
    return math.sqrt(squarex + squarey)

def main():
    p1 = Point(2,3)
    p2 = Point(5,7)
    dist = distance(p1,p2)
    print dist

You run main()

main():
    p1 = Point(2,3)
    p2 = Point(5,7)
    dist = distance(p1,p2)
    print dist

We have now created two points. On the third line, we try to assign a value to the “dist” variable, but to do that, we need to first execute the distance() function.
def square(x):
    return x * x

def distance(p1, p2):
    squarex = square(p2.getX() - p1.getX())
    squarey = square(p2.getY() - p1.getY())
    return math.sqrt(squarex + squarey)

def main():
    p1 = Point(2, 3)
    p2 = Point(5, 7)
    dist = distance(p1, p2)
    print(dist)

You run main()
function definitions:

```python
def square(x):
    return x * x

def distance(p1, p2):
    squarex = square(p2.getX() - p1.getX())
    squarey = square(p2.getY() - p1.getY())
    return math.sqrt(squarex + squarey)

def main():
    p1 = Point(2,3)
    p2 = Point(5,7)
    dist = distance(p1, p2)
    print dist
```

You run `main()`

```python
main():

distance(p1 = main::p1, p2 = main::p2):

    square(x = 3):
        return 9
```

scratch pad:

```
x * x
= 3 * 3
= 9
```

The value of 3 passed to `square()` is bound to `square()`’s formal parameter, `x`. On the scratch pad we compute the return value, and send it back to the calling function.
def square(x):
    return x * x

def distance(p1,p2):
    squarex = square(p2.getX() - p1.getX())
    squarey = square(p2.getY() - p1.getY())
    return math.sqrt(squarex + squarey)

def main():
    p1 = Point(2,3)
    p2 = Point(5,7)
    dist = distance(p1,p2)
    print dist

You run main()

distance(p1 = main::p1, p2 = main::p2):
    squarex = 9

One way to think about what’s happening is to imagine that the function call gets replaced by its return value. Now that we have an actual number (the return value of calling distance()), we can assign the value to squarex and continue to the next line.
You run main()

On the scratch pad we compute the value of \( \text{p2.getY()} - \text{p1.getY()} \) so we can pass that value as an argument to our next invocation of square().
Here we finish our call to square(), just as we did before.
function definitions:

```python
def square(x):
    return x * x

def distance(p1,p2):
    squarex = square(p2.getX() - p1.getX())
    squarey = square(p2.getY() - p1.getY())
    return math.sqrt(squarex + squarey)

def main():
    p1 = Point(2,3)
    p2 = Point(5,7)
    dist = distance(p1,p2)
    print dist
```

You run main()

When the square() function returns, we can assign its value to squarey.
function definitions:

```python
def square(x):
    return x * x

def distance(p1, p2):
    squarex = square(p2.getX() - p1.getX())
    squarey = square(p2.getY() - p1.getY())
    return math.sqrt(squarex + squarey)

def main():
    p1 = Point(2,3)
    p2 = Point(5,7)
    dist = distance(p1, p2)
    print dist
```

main():

```python
distance(p1 = main::p1, p2 = main::p2):
    squarex = 9
    squarey = 16
    return math.sqrt(25)
```

test:

```python
scratch pad:
squarex + squarey
= 9 + 16
= 25
```

On the scratch pad we compute the value of the argument to math.sqrt(). Note that this is another function call, which gets called (and executes) just like our calls to square(), etc. But for purposes of this demonstration, we won’t step into the function, and just take its return value.
def square(x):
    return x * x

def distance(p1, p2):
    squarex = square(p2.getX() - p1.getX())
    squarey = square(p2.getY() - p1.getY())
    return math.sqrt(squarex + squarey)

def main():
    p1 = Point(2, 3)
    p2 = Point(5, 7)
    dist = distance(p1, p2)
    print(dist)

You run main()

math.sqrt() returns its value, and now distance() can return its own value to its caller, main().
**function definitions:**

```python
def square(x):
    return x * x

def distance(p1, p2):
    squarex = square(p2.getX() - p1.getX())
    squarey = square(p2.getY() - p1.getY())
    return math.sqrt(squarex + squarey)

def main():
    p1 = Point(2,3)
    p2 = Point(5,7)
    dist = distance(p1, p2)
    print dist
```

**You run main()**

distance() returns, so we can finish line 3 of main(). Again, you can think of the call to distance() being replaced in the code with its return value, after it completes. This value is then assigned to `dist`. 
function definitions:

def square(x):
    return x * x

def distance(p1, p2):
    squarex = square(p2.getX() - p1.getX())
    squarey = square(p2.getY() - p1.getY())
    return math.sqrt(squarex + squarey)

def main():
    p1 = Point(2, 3)
    p2 = Point(5, 7)
    dist = distance(p1, p2)
    print dist

You run main()

5

Now print can print the value of dist, and this is displayed in our output box.
functions that modify their parameters

This is the subject of Section 6.5.2 in your book. It’s basically an exception or special case to what you’ve been told before.
Think of a variable as a box that can contain a value. A box usually has a name (the name of the variable), and a value (the value that has been assigned to it). A box can only have one value directly inside it. When you create a list, since a variable (box) can only have one value inside it, what happens implicitly behind the scenes is that a bunch of little anonymous boxes are created. The list variable contains all of those little boxes, and those little boxes contain the actual values. This way you obey the rule that a box can only directly have one value.
Think of a variable as a box that can contain a value. A box usually has a name (the name of the variable), and a value (the value that has been assigned to it). A box can only have one value directly inside it. The list variable contains all of those little boxes, and those little boxes contain the actual values. This way you obey the rule that a box can only directly have one value.
Think of a variable as a box that can contain a value. A box usually has a name (the name of the variable), and a value (the value that has been assigned to it). A box can only have one value directly inside it. When you create a list, since a variable (box) can only have one value inside it, what happens implicitly behind the scenes is that a bunch of little anonymous boxes are created. The list variable contains all of those little boxes, and those little boxes contain the actual values. This way you obey the rule that a box can only directly have one value.
When you assign the value of a variable to another variable, it gets the contents of the box. When you assign \(a2 = a\), a new box \(a2\) gets the same value as \(a\). They are independent; changing \(a2\) will not change \(a\), nor vice versa. But when you assign \(b2 = b\), each contains the anonymous list of boxes, so changing the contents of one will change the other.
This is the old story, which we are about to amend. When variables are passed in to a function, an assignment (of the actual parameters to the function’s formal parameters) is made. This means that changes made within the function to certain kinds of parameters will actually be reflected in the caller’s variables, as well.
This is the old story, which we are about to amend. When variables are passed in to a function, an assignment (of the actual parameters to the function’s formal parameters) is made. This means that changes made within the function to certain kinds of parameters will actually be reflected in the caller’s variables, as well.
def change(num):
    num = num * 2

def main():
    mynum = 7
    change(mynum)
    print mynum

def change(list):
    if (len(list)):
        list[0] = list[0] * 2;

def main():
    mylist = [7, 6, 5, 4, 3]
    change(mylist)
    print mylist[0]

running main() prints
running main() prints

This code exemplifies this point.
This code exemplifies this point.
This code exemplifies this point.
Here is the new story for how information gets into and out of a function. See the next slide for which kinds of variables fall into which category.
Old Story

- Parameters are passed from the caller to the callee by value, not by identity.
- Changes made to those parameters in the callee are not visible to the caller.

Here is the new story for how information gets into and out of a function. See the next slide for which kinds of variables fall into which category.
Here is the new story for how information gets into and out of a function. See the next slide for which kinds of variables fall into which category.
Immutable (passed by value)

**fixed types:**
- integer 29
- float 29.0
- tuple (-4, 2.1, 'test')

Immutable types (rocks) are atomic units. Assignment of these types of items creates independent copies, so that the assigner and assignee have different copies, and changes made to one will not be seen by the other. Mutable types (houses) will be shared. This is, for example, why you can’t create a Rectangle object, draw it, assign it to a new variable, and then draw it again. You have to call clone(), a special function which actually does create a real copy.
### Immutable (passed by value)

#### Fixed types:
- **integer**: 29
- **float**: 29.0
- **tuple**: (-4, 2.1, 'test')

### Mutable (can be modified)

#### Objects:
- **class**: `Point()`
- **list**: `[-4, 2.1, 'test']`

Immutable types (rocks) are atomic units. Assignment of these types of items creates independent copies, so that the assigner and assignee have different copies, and changes made to one will not be seen by the other. Mutable types (houses) will be shared. This is, for example, why you can’t create a Rectangle object, draw it, assign it to a new variable, and then draw it again. You have to call `clone()`, a special function which actually does create a real copy.
Let's consider an example. Most of us have probably heard the story of how the names of immigrants were changed by inspectors at Ellis Island to reflect a more assimilated Westernized spelling and pronunciation. These stories are probably somewhat apocryphal, but we'll ignore that for the moment and write a function that helps out the inspectors.
def assimilate_foreigner(names):
    changed = 0
    for i in range(len(names)):
        if names[i] == ‘Nüchter’:
            names[i] = ‘Nickter’
            changed += 1
        elif names[i] == ‘Wojciechowski’:
            names[i] = ‘Smith’
            changed += 1
        elif names[i] == ‘Hitler’:
            names[i] = ‘Hunter’
            changed += 1
    return changed

This function takes a list of names that would be hard to pronounce for an 18th or 19th century English–speaking Westerner (or, in the case of Hitler, a name which would be undesirable at some point in the future), and changes them. Since names is a list, changes made to it in the function will be also changed in the caller’s list. We also count the number of changes we made.
def suggest_assimilated_names(names):
    # make an independent copy
    newnames = list(names)
    changed = 0
    for i in range(len(names)):
        if names[i] == 'Nüchter':
            newnames[i] = 'Nickter'
            changed += 1
        elif names[i] == 'Wojciechowski':
            newnames[i] = 'Smith'
            changed += 1
        elif names[i] == 'Hitler':
            newnames[i] = 'Hunter'
            changed += 1
    
    return changed, newnames

This function just makes suggestions, instead of forcing the change. Notice that we avoid making copies in the caller’s list by explicitly creating a real copy with the list() function.
Recursion is the definition of a function or object in terms of itself. It is a relatively easy concept to understand, but to really be able to apply it in computer science takes some considerable work and persistence. If you don’t understand this, it might help to know that it takes even computer science majors a lot of time to really be able to use it. Try writing your own functions, make diagrams and drawings, and go over it again and again.
this is seriously the most awesome concept in computer science

It really is.
recursion trivia

• a limitless fount of esoteric computer science humor
  ❖ dictionary definition
  recursion, n. See “recursion”.
  ❖ try Googling “recursion” (after today’s lecture)

• recursive acronyms
  ❖ GNU = “GNU’s not UNIX”
  ❖ pine = “pine is not elm”

• also a property of language, is found in nature, and serves as the foundation for a class of mathematical proofs

Here are some examples of recursion.
function definitions:

```python
def fun():
    fun()

def main():
    fun()
```

You run `main()`

In the remainder of the talk, we are going to build a function that computes the sum of the first `n` integers. You may recall that this can be computed directly with the function `n * (n + 1) / 2` (e.g., the sum of the first 10 integers is `10 * 11 / 2 = 55`).

We start with a simple but useless example of recursion. If you ran this program, it would never stop, because each instance of `fun()` just calls itself again. Eventually your computer will run out of memory and might give you an error like this one.

You run main()

FATAL ERROR UNBOUNDED RECURSION!

but again, it never stops, and we get another instance of unbounded recursion.
we need a base case

Recursion is still pretty useless to us. We need a way to allow a function to call itself, but also a way to eventually stop. This is called the base case.
Here we have added a base case: when the parameter is 1, the function returns 1. You will notice that this base case is useful: if we wanted to know the sum of the first 1 integers, we would call fun(1), and it would return 1, which is the correct answer. Even though this is trivial, identifying the base case like this is crucial to developing a recursive algorithm.

You will notice that this base case is useful: if we wanted to know the sum of the first 1 integers, we would call fun(1), and it would return 1, which is the correct answer. Even though this is trivial, identifying the base case like this is crucial to developing a recursive algorithm.
function definitions:

def fun(x):
    if x == 1:
        return 1
    fun(x - 1)
    return None

def main():
    fun(10)

You run main()

scratch pad:

Now, what happens when we call fun(2)? x is not 1, so we skip to the third line, call fun(2-1) (which is fun(1)). That returns 1, but we are not doing anything with it! Instead, we are returning None.
Now, what happens when we call `fun(2)`? `x` is not 1, so we skip to the third line, call `fun(2-1)` (which is `fun(1)`). That returns 1, but we are not doing anything with it! Instead, we are returning None.
function definitions:

def fun(x):
    if x == 1:
        return 1
    fun(x - 1)
    return None

def main():
    fun(10)

You run main()
You run main()
we need to return something in the recursive case, too

We need to return a value, not just in the base case, but in the recursive case as well.
Here we have made this change: now our function will always return something. However, it’s not quite the right value.
Here we have made this change: now our function will always return something. However, it's not quite the right value.
def fun(x):
    if x == 1:
        return 1
    return fun(x - 1)

def main():
    fun(10)

You run main()

When we call fun(1), we still get the right answer, but fun(2) returns 1 as well, which isn't correct.
**function definitions:**

```python
def fun(x):
    if x == 1:
        return 1
    return fun(x - 1)

def main():
    fun(10)
```

**You run main()**

When we call `fun(1)`, we still get the right answer, but `fun(2)` returns 1 as well, which isn’t correct.
function definitions:

def fun(x):
    if x == 1:
        return 1
    return fun(x - 1)

def main():
    fun(10)

You run main()

Same for fun(3), and all the way back up to the original call fun(10).
function definitions:

def fun(x):
    if x == 1:
        return 1
    return fun(x - 1)

def main():
    fun(10)

You run main()

Same for fun(3), and all the way back up to the original call fun(10).
we need to actually *do something* with the results we’ve computed

The recursive case needs to return a different value. That is, it finds out the value of the subproblem, and then needs to add / multiply / otherwise manipulate that value so that it’s caller can get a different answer.
def fun(x):
    if x == 1:
        return 1
    return x + fun(x - 1)

def main():
    n = 10
    sum = fun(n)
    print "sum of first", n,
    print "integers is", sum

The way to do that is to add our own value of x to that of the recursive call. Think of it this way. What is the sum of the first 1 integers? 1. What is the sum of the first two integers? 2 + 1. What is the sum of the first three integers? 3 + 2 + 1. First four? 4 + 3 + 2 + 1. You’ll notice that in each case, the answer to “What is the sum of the first n integers?” is “n + the sum of the first (n-1) integers”. That’s our recursive formulation.
def fun(x):
    if x == 1:
        return 1
    return x + fun(x - 1)

def main():
    n = 10
    sum = fun(n)
    print "sum of first", n,
    print "integers is", sum

You run main()

fun(x = 2):
    return 2 + fun(1)

2 + fun(1)
= 2 + 1
= 3

Here we see the correct value for fun(2) getting passed up to its caller, fun(3). The scratch pad computes the third line of the function fun(), which it can do now that it’s subcall to fun() has returned.
def fun(x):
    if x == 1:
        return 1
    return x + fun(x - 1)

def main():
    n = 10
    sum = fun(n)
    print "sum of first", n,
    print "integers is", sum

You run main()

And so on up the chain of calls.
def fun(x):
    if x == 1:
        return 1
    return x + fun(x - 1)

def main():
    n = 10
    sum = fun(n)
    print "sum of first", n,
    print "integers is", sum

= 8 + 28
= 36
def fun(x):
    if x == 1:
        return 1
    return x + fun(x - 1)

def main():
    n = 10
    sum = fun(n)
    print "sum of first", n,
    print "integers is", sum

You run main()

scratch pad:

fun(x = 9):
    return 9 + fun(8)

9 + fun(8)
= 9 + 36
= 45
function definitions:

def fun(x):
    if x == 1:
        return 1
    return x + fun(x - 1)

def main():
    n = 10
    sum = fun(n)
    print "sum of first", n,
    print "integers is", sum

You run main()

scratch pad:

fun(x = 9):
    return 45

9 + fun(8)
= 9 + 36
= 45
function definitions:

def fun(x):
    if x == 1:
        return 1
    return x + fun(x - 1)

def main():
    n = 10
    sum = fun(n)
    print “sum of first”, n,
    print “integers is”, sum

You run main()

scratch pad:

fun(x = 10):
    return 10 + fun(9)

10 + fun(9-1)
= 10 + 45
= 55
function definitions:

```python
def fun(x):
    if x == 1:
        return 1
    return x + fun(x - 1)

def main():
    n = 10
    sum = fun(n)
    print "sum of first", n,
    print "integers is", sum
```

You run main()

```
main():
    fun(x = 10):
        return 55
```

scratch pad:

```plaintext
10 + fun(9-1)
= 10 + 45
= 55
```
Finally, the initial call to fun(10) returns with the correct value. This is assigned to the variable `sum`, which is then printed out.
def fun(x):
    if x == 1:
        return 1
    return x + fun(x - 1)

def main():
    n = 10
    sum = fun(n)
    print "sum of first", n,
    print "integers is", sum

You run main()

sum of first 10 integers is 55
summary

- **function parameters:** *fixed, atomic types* vs *object types*
  - objects passed to functions are mutable
  - fixed types are not
- **recursion**
  - solves a larger problem in terms of a smaller one
  - argument must change each time (to avoid an infinite loop)
  - the changing argument value must be approaching the base case
  - should return the result of the sub function call plus something else
