

# The Halting Problem

## The Halting Problem

We will show that **the problem of determining whether or not a given Turing machine accepts a given input is unsolvable**.

In other words, there is no Turing machine (and hence no algorithm) that decides

$$A_{\text{TM}} = \{ \langle M, w \rangle \mid M \text{ is a Turing machine and accepts } w \}.$$

(Later, we use this result to conclude that **the halting problem**, i.e., determining whether or not a given TM halts on a given input, is also unsolvable.)

The method of proof involves the technique of **diagonalization**, so we begin with this topic.

## Diagonalization

A set is **countable** if either it is finite or it has the same size as  $\mathcal{N}$ ; i.e., there is a **one-to-one mapping** from the set **onto**  $\mathcal{N}$  (in other words, there is a **bijection** from the set to  $\mathcal{N}$ ).

**Fact.** *Let  $\mathcal{Q}$  be the set of all positive rational numbers and  $\mathcal{R}$  the set of all positive real numbers. Then  $\mathcal{Q}$  is countable while  $\mathcal{R}$  is not.*

**Proof** For the former, each member of  $\mathcal{Q}$  is expressed as a fraction  $\frac{m}{n}$  such that  $m, n \in \mathcal{N}$  and  $\gcd(m, n) = 1$ .

So we have only to come up with a bijection from  $\mathcal{N}$  to the set  $\{\frac{m}{n} \mid m, n \geq 1 \text{ \& } \gcd(m, n) = 1\}$ .

## $\mathbb{Q}$ is countable

For  $p = 1, 2, \dots$ , visit the integral points on the line  $m + n = p$  in the first quadrant of the  $xy$ -plane and count how many pairs  $(m, n)$  such that  $\gcd(m, n) = 1$  have been seen.

## $\mathcal{R}$ is not countable (proof by diagonalization)

For the latter, assume, for contradiction, that  $\mathcal{R}$  is countable. Let  $f$  be a bijection from  $\mathcal{R}$  to  $\mathcal{N}$ . For each  $i \in \mathcal{N}$ , let  $r_i = f^{-1}(i)$ . Define  $x$  to be the number between 0 and 1 defined as follows:

(\*) **For every  $i \in \mathcal{N}$ , the  $i$ th digit of  $x$  after the decimal point in its decimal representation is that of  $r_i$  plus 1 (modulo 10).**

For example, if  $r_1 = 3.\underline{1}4159$ ,  $r_2 = 2.2\underline{3}606$ ,  $r_3 = 1.73\underline{2}05, \dots$ , then  $x = .243\dots$ ,

This  $x$  is real. By assumption there is a unique  $k$  such that  $x = f^{-1}(k)$ . Then by definition

(!!) *the  $k$ th digit of  $x$  is the  $k$ th digit of  $x$  plus 1 modulo 10,*  
which is a contradiction. So,  $\mathcal{R}$  is not countable. 

## An Immediate Application of Diagonalization

**Corollary.** *There is a language that is not Turing-recognizable.*

**Proof** The set of Turing machines is countable:

1. Fix an encoding scheme of Turing machines on an alphabet  $\Sigma$ .
2. **Go through all the strings in  $\Sigma$** , e.g., in lexicographic order, and **assign numbers to all legal encodings** by counting **how many legal encodings have been seen so far**.

A language over  $\Sigma$  can be viewed as an infinite binary number  $0.b_1b_2b_3\cdots$ , called the **characteristic sequence**, where for each  $i \geq 1$ ,  $b_i$  corresponds to the membership of the  $i$ th string in the language. So the languages have the same cardinality as the set of binary reals between 0 and 1, which is uncountable. 

**Theorem.** *The language*

$$A_{\text{TM}} = \{ \langle M, w \rangle \mid M \text{ is a Turing machine and accepts } w \}$$

*is not decidable.*

**Proof** Assume that  $A_{\text{TM}}$  is decidable. Let  $T$  be a Turing machine that decides  $A_{\text{TM}}$ . Define  $D$  to be a machine that, on input  $w$ ,

1. Checks whether  $w$  is a legal encoding of some Turing machine, say  $M$ . If not,  $D$  immediately rejects  $w$ .
2. Simulates  $T$  on  $\langle M, \langle M \rangle \rangle$ .
3. If  $T$  accepts, then  $D$  rejects; otherwise, it accepts.

Since  $T$  decides  $A_{\text{TM}}$  by assumption, it always halts; so does  $D$ .

## Proof that $A_{\text{TM}}$ is undecidable, cont'd

For every Turing machine  $M$ ,

$D$  accepts  $\langle M \rangle \Leftrightarrow M$  does not accept  $\langle M \rangle$

With  $M = D$ , we have

$D$  accepts  $\langle D \rangle \Leftrightarrow D$  does not accept  $\langle D \rangle$ .

This is a contradiction. ■

**Corollary.**  $\overline{A_{\text{TM}}}$  is not Turing-recognizable, and thus, not decidable.

For this corollary we need the following fact.

**Fact.** A language  $L$  is decidable if and only if both  $L$  and  $\overline{L}$  are Turing-recognizable.

**Proof of Corollary**  $A_{\text{TM}}$  is Turing-recognizable and is not decidable.  
So,  $\overline{A_{\text{TM}}}$  is not Turing-recognizable ■Corollary

**Proof of Fact**  $[\Rightarrow]$  Let  $L$  be decidable and let  $M$  be a Turing machine that decides  $L$ . By swapping  $q_{\text{accept}}$  and  $q_{\text{reject}}$  of  $M$  we get a Turing machine  $M'$  that decides  $\bar{L}$ . So both  $L$  and  $\bar{L}$  are Turing-decidable, and thus, Turing-recognizable.

$[\Leftarrow]$  Let  $L$  and  $\bar{L}$  be recognized by TMs  $M_1$  and  $M_2$ , respectively. Define a two-tape machine  $M$  that, on input  $x$ , does the following:

1.  $M$  copies  $x$  onto Tape 2.
2.  $M$  repeats the following until either  $M_1$  or  $M_2$  accepts:
  - (a)  $M$  simulates one step of  $M_1$  on Tape 1 then one step of  $M_2$  on Tape 2.
3.  $M$  accepts  $x$  if  $M_1$  has accepted and rejects if  $M_2$  has accepted.

Then  $M$  decides  $L$  because for every  $x$ , at least one of the two machines halts on input  $x$ .

 **Fact**
