Classic Compiler Architecture

Recommended reading: Chris Lattner, LLVM, The Architecture of Open Source Applications

Introduction

Midend

Miscellaneous

- Mostly language and machine independent analyses
- Majority of analyses run in this stage
- Multiple intermediate representations used
 - Starts from abstract syntax tree
 - Usually stops before instruction scheduling/register allocation
 - Examples: AST, CFG, DDG, PDG, etc.
- There is no one Intermediate Representation (IR)
 - although people have tried ...

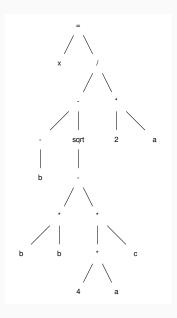

- Organized as a set of *passes*
- Each pass usually performs one task
 - Some specific analysis of the IR
 - Some transformation of the IR
- Input to each pass is the IR and output is also the IR
 - And usually analysis results, etc.

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

In Python (assume math.sqrt is sqrt):

x = (-b - sqrt(b*b - 4 * a * c)) / (2*a)

Abstract Syntax Tree

AST as a list

```
ast = ['=',
        ['x',
          ['/',
           ['-',
             ['neg', 'b'],
             ['sqrt',
              ['-',
               ['*<sup>'</sup>, 'b', 'b'],
               ['*',
['*', '4', 'a'],
                 , c,
          ]
]
],
['*', '2', 'a']
```

• What does this remind you of?

```
class Node(object):
    operator = None
    left = None
    right = None
```

- Actual ASTs are not binary trees!
 - Will usually have list of descendants instead of left and right
 - descendants may be more specific, while may have condition and body

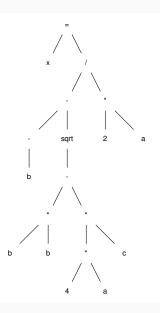

- ASTs imply treewalking
 - Works best when manipulating source code
 - e.g. Source-to-source compilers
 - Or when control flow is not important
- Other lower level forms are "closer to machine"
 - Stack machines
 - 3 address code

push a push 2 mul push c push a push 4 mul push b push b m11] sub sqrt push b neg sub div рор х

How do you produce stack machine code from an AST?

Generating Stack Machine Code

push a push 2 mul push c push a push 4 mul mul push b push b mul sub sqrt push b neg sub div рор х

- Compact in size
 - Operands are implicit on top of stack.
- Easy to execute
- BUT, fixed order of execution
 - Bad for parallelism
- Hard to analyze
- Nevertheless, widely used:
 - Java bytecode
 - Python bytecode
 - WebAssembly

- 3 "addresses"
 - Two source operands
 - One destination operand
 - One operation
- Addresses are actually names generated by compiler
 - Or refer directly to variables

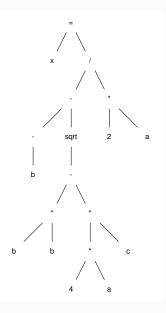

t1 <- -b
t2 <- b * b
t3 <- 4 * a
t4 <- t3 * c
t5 <- t2 - t4
t6 <- sqrt(t5)
t7 <- t1 - t6
t8 <- 2 * a
t9 <- t7 / t8
x <- t9</pre>

(Here '<-' is \leftarrow , signifying assignment)

How do we produce 3-address code from the AST?

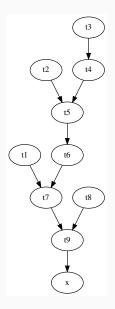

Producing 3-address code

t1 <- -b
t2 <- b * b
t3 <- 4 * a
t4 <- t3 * c
t5 <- t2 - t4
t6 <- sqrt(t5)
t7 <- t1 - t6
t8 <- 2 * a
t9 <- t7 / t8
x <- t9</pre>

Data Dependence Graphs (DDGs)

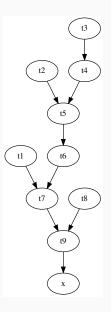

- DDGs track "data flow" as an acyclic graph
- Strict (partial) order in which operations must be performed
 - Can't use a value that has not been calculated yet!
- But multiple orders may be allowed!
 - Topological sort
- Will revisit DDGs when we discuss instruction scheduling

t1 <- -b
t2 <- b * b
t3 <- 4 * a
t4 <- t3 * c
t5 <- t2 - t4
t6 <- sqrt(t5)
t7 <- t1 - t6
t8 <- 2 * a
t9 <- t7 / t8
x <- t9</pre>

DDG Example, reordered by dependence

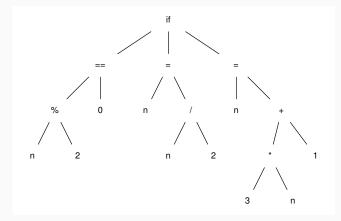

```
# group 1
t1 <- -b
t2 <- b * b
t3 <- 4 * a
t8 <- 2 * a
# must wait for t3
t4 <- t3 * c
# must wait for t4 and t2
t5 <- t2 - t4
# ...
t6 <- sqrt(t5)
t7 <- t1 - t6
t9 <- t7 / t8
x <- t9
```

What should the 3 address code for the code below look like?

```
if n % 2 == 0:
    n = n / 2
else:
    n = 3 * n + 1
```

The AST for if

• An if AST node has a condition, true-code, and false-code

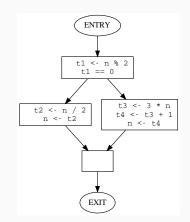

3-Address Code for if

```
t1 <- n % 2
tc <- t1 == 0
if (tc == 0) goto L1
t2 <- n / 2
n <- t2
goto L2
L1:
t3 <- 3 * n
t4 <- t3 + 1
n <- t4
L2:
```

- 3-address code can contain:
 - conditional branches, usually just a comparison to zero
 - unconditional branches
 - labels

Control Flow Graphs (CFGs)

- "Hybrid" representation
 - Linear code + Graph structure
- Each node in the CFG is a "basic block"
 - Linear code
 - Single entry, single exit
 - "Straight-line code"
- Most common form for analysis

- We will write midend + some bits of a backend
- Input language: C
- Output language: C in 3-address form
 - Not assembly (maybe extra credit?)
- Using Python library pycparser

- Basic data structures
 - lists
 - trees
 - graphs
- Basic data structure traversals
 - Infix, prefix, postfix
 - Depth-first, breadth-first
- And how to implement them in Python
 - Using Python standard libraries is fine

Introduction

Midend

Miscellaneous

What is this code from TensorFlow doing?

```
a = tf.constant(2)
b = tf.constant(3)
with tf.Session() as sess:
    print("a=2, b=3")
    print("Addition with constants: %i" % sess.run(a+b))
    print("Multiplication with constants: %i" % sess.run(a*b))
```

https://github.com/aymericdamien/TensorFlow-Examples/blob/master/examples/1_Introduction/basic_ operations.py

- TensorFlow API builds a graph
 - directed, acyclic
 - similar to the DDG
 - very common technique
- When sess.run is called, graph is compiled and executed
- Advantages:
 - No syntax, no parsing!
- Disadvantages:
 - ?

What about functional programming languages?

- General problem is to represent control transfers as function calls
- Continuation Passing Style
 - Each basic block is a function that accepts a *continuation*, another function
 - At end of each basic block/function, the continuation is called
- Later we'll learn about SSA which is easy to transform into this style
 - See Appel (1998), SSA is functional programming*
- Another representation is *A-normal Form*
 - Cormac, Sabry, Duba, Felleisen (1993), The Essence of Compiling with Continuations
 - Interesting usage: McMahan et al. (2017), An Architecture Supporting Formal and Compositional Binary Analysis

- Chapter 5 of Cooper and Turczon
 - Up to 5.4 in this lecture, but we will ultimately study the whole chapter
- Note that * next to paper citations means that the paper is in the syllabus for 4xx students
